9/15/2018
Impact of Wildlife-Vehicle Conflict on California Drivers and Animals

Using observations of reported traffic incidents and carcasses the Road Ecology Center estimates the total annual cost (2017) of wildlife-vehicle conflict (WVC) in California to be at least $307 million, up 11% from 2016. The cost is calculated using CHP reports of crashes with wildlife and US Department of Transportation equivalent values for different types of crashes (e.g., property damage vs. major injury). The estimated cost could be as high as $600 million if accidents that are claimed to insurance companies (but un-reported to police) were included. This report includes maps of WVC hotspots, discusses impacts to wildlife and people from WVC, and presents new tools to help organizations, state agencies and individuals use this information. Projects to reduce WVC can be the most effective of any safety project, with effectiveness often >90%.

Data Sharing/Collaboration: We are always happy to share data and map outputs for people interested in reducing WVC for driver safety and/or wildlife conservation. We receive requests from highway planners, fish and wildlife scientists, academic faculty, students, and non-governmental organizations on a weekly basis. We can typically meet data requests within CA, USA for specific highways, counties, etc., but please keep in mind that this is an unfunded effort of the Road Ecology Center, so we will try to get back to you within a few days.

We have developed a globally-unique web-tool to visualize WVC incidents in CA. It shows WVC hotspot areas throughout CA and a real-time display of WVC events. You can find the website here: https://roadecology.ucdavis.edu/hotspots.

Thanks to our great peer reviewers for improving the rigor and readability of the report: Bridget Donaldson (Virginia DOT/Virginia Transportation Research Council), Jeff Gagnon (Arizona Game and Fish Department), Hoe Hun Ha (Auburn University), Wendy Collinson (Endangered Wildlife Trust, South Africa).
This report provides an overview of wildlife-vehicle conflict (WVC) hotspots on California highways between 2015 and 2017, inclusive, based on a combination of traffic incidents involving wildlife that were recorded by the California Highway Patrol (CHP) and carcass observations reported to the California Roadkill Observation System (CROS, http://wildlifecrossing.net/california). Analytical details are provided here and are also available from Fraser Shilling (fmshilling@ucdavis.edu) upon request. This report also introduces a new, public web-system that allows the public and transportation agencies to view our scientific results for both legacy/long-term hotspots analysis and real-time tracking of WVC incidents.

Data collection acknowledgements

We appreciate the support from the National Center for Sustainable Transportation (using USDOT funding) for development of the automated wildlife-vehicle conflict hotspot tool described here and elsewhere. This and previous reports and the analyses contained within would not have been possible without the concerted and coordinated efforts of hundreds of volunteer roadkill observers over the last 9 years who contribute to the California Roadkill Observation System (CROS, http://wildlifecrossing.net/california). Through their endeavors, they have so far (9/2018) collected >58,000 observations of >420 species, representing one of the largest and most comprehensive wildlife monitoring programs in California and the US. Their accuracy rates for species identification are >97% and have measurably high locational accuracy (median <+13 meters). For scientific papers describing our roadkill/WVC work, see our published work cited below and at the end of this report (you can paste the “doi” value into a browser and access the papers). The report also benefited from the efforts of many unknown law enforcement personnel who described traffic incidents in enough detail that we can use their observations to help plan for reduced wildlife-vehicle conflict.

CROS is 9-Years Old, Published, & Globally Linked

The Road Ecology Center at UCD is happy to announce that CROS passed its 9th birthday, and during this period, the volunteers have assembled an (ongoing) important dataset which can benefit California wildlife and drivers in the decades to come. We have published our data and findings in the peer-reviewed journals Ecological Informatics, Nature Conservation, and Frontiers of Ecology and Evolution, covering the technical details of the project, including the accuracy of volunteer observations. Finally, we have partnered with other similar systems around the world in the Globalroadkill.net project (http://globalroadkill.net).

## The Authors

Fraser Shilling is the Co-Director of the UC Davis Road Ecology Center (http://roadecology.ucdavis.edu) and actively investigates the impacts of transportation systems on natural systems and human communities. He received his PhD in 1991 from the University of Southern California in the Division of Biological Sciences. Cameron Denney is a newly-graduated M.Sc. student in Geography at UC Davis and pioneered our new “automated hotspots” web-tool. David Waetjen is lead programmer and web guru for the Road Ecology Center. He received his PhD from UC Davis (Geography) in 2011. He develops web-systems and spatial analyses for wildlife, water, and sustainability applications. Kathryn Harrold is an independent wildlife consultant who is expert in how wildlife interact with roadways and how we can improve roads/highways to protect drivers and wildlife from conflict. Undergraduate and recently-graduated students Parisa Farman and Paola Perez are pursuing careers in wildlife biology and environmental policy. Read more about staff here: https://roadecology.ucdavis.edu/people.

Top 5 Recommendations

1) **Systematically collect and share data.** The state data assembled here were not collected with the purpose of studying wildlife-vehicle conflict, the volunteer data were. California agencies should collect and share data about wildlife-vehicle conflict to help inform decision-making about this important conservation and safety problem. We are open to partnering with Caltrans, California Department of Fish and Wildlife and others to accomplish this.

2) **Require collection and analysis of wildlife-vehicle conflict data for highway/road projects, before they are approved and funded.** Transportation and wildlife agency biologists have very little data upon which to base decisions for projects impacting wildlife. Highway projects that are likely to increase WVC can be built because these data are not required.

3) **Protect driver safety and wildlife by building WVC-reduction projects.** Very few driver safety projects have the overall effectiveness that WVC reduction projects do. There are hundreds of places on state highways and major roads where WVC is a priority, but statewide only 2-3 projects are built per year. Ten times that rate would make a dent in the apparent risk to both drivers and wildlife.

4) **Form new partnerships** among University and NGO scientists, citizen groups, and local agencies interested in reducing WVC impacts. Local, statewide and international partners can help advocate for diversion of transportation funds to investigate and improve ecological sustainability of transportation.

5) **Systematically evaluate how well we are doing with WVC reduction** so that we can keep improving. As we plan and build WVC reduction, we should transparently monitor reduced driver injuries and death and use of the structures by wildlife.

Introduction to Study

Using California state data on traffic incidents, the Road Ecology Center has mapped stretches of 15,160 miles of California highways that are likely to be continued hotspots for wildlife-vehicle conflicts (WVC). Animals entering roadways are often killed and pose a hazard to drivers, who may collide with the animal, or try to avoid the animal suffering vehicle damage, injury, and even death. Wildlife populations may suffer significant losses from highways with high rates of WVC, which may cause ripple effects into surrounding ecosystems. In addition, animals are injured during collisions, which is damaging to the animal and traumatic and deadly to drivers.
By identifying stretches of highway where WVC are more likely, the Road Ecology Center is assisting Caltrans and other responsible entities in developing mitigation to protect drivers and wildlife populations. Measures with proven effectiveness include building fencing and over/under-passes along priority highways to allow the safe passage of wildlife across highways and reducing speed limits in protected wildlife habitat. Using CHP data, we have found records of >6,600 reported accidents per year on California highways involving deer and other wildlife. We estimate that there are another few thousand with horses, cows, sheep and goats. Data from the California Roadkill Observation System also allow us to prioritize priority stretches of highway for mitigation of species or group-specific conflicts (e.g., Ha and Shilling, 2017).

We have determined rates and locations of both animal carcasses and reported traffic incidents. These incidents could be reports of animals running across the road, collisions with animals (primarily deer), or accidents resulting from people swerving to avoid a collision with an animal in the road. Because deer activity adjacent to highways is correlated with rates of collisions with deer (Donaldson et al., 2015), we included CHP reports of live animals on or near highways (~10% of all reports). Our analyses include identification of geographical hotspots and calculated costs to the public from vehicle damage, injury and even death. This information shows where there are problems and should help in developing safety projects to fix known problem areas.

We estimated the total annual cost to society from >6,600 WVC incidents in California on state highways and a small proportion of major roads. It is important to note that this report does not cover ALL incidents in California, just incidents with large animals reported by the CHP and California Roadkill Observation System (CROS). State Farm Insurance Co. estimated that California had >23,000 claims/year for collisions with large wildlife in 2015-2016, which is >3 times the rate we describe here and does not include collisions with small animals (https://newsroom.statefarm.com/download/234883/allstates2015-16deerstats-finalpdf.pdf). Thus we suspect that we are under-estimating the total cost of these types of accidents. This contrast points to the need for a standardized system for California to collect and report data about WVC and animal carcasses.

The following sections include maps of the distribution of WVC densities, projected costs of WVC and hotspots along state highways and other roadways. The densities of WVC reported are the minimum for each highway segment and do not represent actual rates, which are likely to be much higher. By significantly increasing the systematic treatment of these hotspots and stretches of highway with high rates of collisions, Caltrans and other entities can contribute cost-effectively to driver safety and improve the environmental sustainability of state highways.
Methods

Traffic Incidents

Records of traffic incidents between February 2015 and December 2017 were obtained from state databases of traffic incidents (e.g., emergency responses to crashes), included in our customized “California Highways Incident Processing system” (CHIPs), and coded according to severity of the incident for the drivers/vehicles and for the animals. For this ~3 year period, we separated the ~19,800 records of wildlife-vehicle collisions from the ~2.5 million traffic incidents using customized term queries (e.g., for “deer” AND “buck” AND “doe” AND “fawn”). We reviewed each record for information about fate of the animal, fate of the driver, type of accident (collision vs. swerve), and vehicle damage. Location and date/time information were from the incident record.

The California Roadkill Observation System project (http://wildlifecrossing.net/california) includes past and current participation by over 1,000 volunteer-scientists, including several hundred academic, agency, and NGO biologists and natural historians (Waetjen and Shilling, 2017). More than 56,000 WVC observations were contributed to the website by volunteers between August 2009 and the end of 2017 and by Caltrans Maintenance staff for the period 1987 to 2007. We selected recent (last three years) observations of large-animal carcasses (e.g., black bear) and combined these observations with the CHP crash data. We carefully controlled for duplicates, which were only rarely found because animal carcasses from crash incidents were usually collected fairly quickly by Caltrans.

The carcass observations and traffic incidents were used in a geographic information system (GIS) to identify stretches of highway where WVC occur more frequently (high density) and places where there are statistically-significant clusters of WVC (hotspots; Shilling and Waetjen, 2015). Density was calculated as number of incidents/mile and by using the Kernel Density Estimator (KDE) tool in ArcGIS. Hotspots were identified using the spatial autocorrelation test Getis-Ord for 1 mile state highway segments. This length of highway segment was chosen because most highway planning occurs at this scale. Specific methods are included in a methodology appendix. Estimates of costs to society of incidents were calculated using the nature of the incident (e.g., “minor injury”) and coefficients for the average cost of these types of incidents used by the US Department of Transportation (USDOT, 2013) and in published literature (Huijser et al., 2009) and technical reports (Cramer et al., 2016).

More methodological details are provided in the Appendix at the end of this report.
Major Findings

We estimated the total annual cost to society from >6,600 WVC incidents in California on state highways and a small proportion of major roads to be ~$307 million for 2017, which is an 11% increase compared to 2016. State Farm Insurance Co. estimated that California had >23,000 claims/year ([https://newsroom.statefarm.com/download/234883/allstates2015-16deerstats-finalpdf.pdf](https://newsroom.statefarm.com/download/234883/allstates2015-16deerstats-finalpdf.pdf)) for collisions with wildlife in 2015-2016, which is >3 times the rate we found and if included, would result in a total cost to society of ~$600 million/year. In addition, we counted 268 injury accidents in the CHP data we used, less than the 383 injuries Caltrans reported in a 2018 press release using CHP data ([http://www.dot.ca.gov/paffairs/pr/2018/prs/18pr072.html](http://www.dot.ca.gov/paffairs/pr/2018/prs/18pr072.html)). Thus we under-estimate the injury portion of the total cost of these types of accidents by ~1/3.

Statewide Carcass Observations

The maps below show >56,000 observations of animal carcasses on local roads and state highways (Figure 1). These are not the total roadkill that occurred, just the ones that people saw and reported to the California Roadkill Observation System (CROS) between 2009 and 2017.

![Figure 1. Carcass observations for (A) amphibians, reptiles, and birds; and (B) mammals.](image1.png)

Statewide Highway Traffic Incidents

There were >2 million traffic incidents (of all types) across California reported to the CHP in 2015-2017. Of these, about half were collisions and more than 19,800 involved wildlife, including reports of animals standing next to (potential incidents), standing in, or running across roadway lanes, collisions with large animals, and swerving to avoid collisions, resulting in a crash (Figure 2, Wildlife-vehicle conflicts). The fall (Sept-Nov) is the most likely time for deer-vehicle conflict, due to increased movement related to mating seasons and seasonal migration.
For the first time, we also developed hotspot maps for animal-vehicle-conflict (AVC) involving domestic animals in free range areas, or that have escaped enclosures. Domestic cattle, horse, sheep, pigs and goats can all become involved in conflict incidents with traffic. We are still determining how to separate incidents with feral horses and pigs from those with escaped domestic animals. Because some of these animals can be quite large, larger than most wildlife (expect elk and some bears), collisions with them can be particularly severe for the drivers. We found that AVC occurs on most/all highways in California (Figure 3) and at fairly high rates.

Figure 2. Wildlife-vehicle conflict incidents (including feral pigs) on state highways (2015-2017)
Although WVC occurs on every major road and highway in California, the highest densities were reported in the San Francisco Bay Area (Caltrans District 4), Sierra Nevada Foothills (Caltrans Districts 3 & 10), North Coast (Caltrans District 1), and parts of the Central/South Coast (Caltrans Districts 5, 7, 11 & 12). These high-density areas are most likely where traffic volumes and wildlife populations are greatest, leading to more conflict. The map below shows the high-density clusters of collisions with large wildlife in California (Figure 4).

**Figure 3.** Animal-vehicle conflict involving domestic animals (cows/cattle and horses) for 2015 - 2017.

**Statewide Wildlife-Vehicle Conflict Hotspots**

Although WVC occurs on every major road and highway in California, the highest densities were reported in the San Francisco Bay Area (Caltrans District 4), Sierra Nevada Foothills (Caltrans Districts 3 & 10), North Coast (Caltrans District 1), and parts of the Central/South Coast (Caltrans Districts 5, 7, 11 & 12). These high-density areas are most likely where traffic volumes and wildlife populations are greatest, leading to more conflict. The map below shows the high-density clusters of collisions with large wildlife in California (Figure 4).
Figure 4. Statistically-significant, high-density WVC hotspots for 2015 to 2017. Hotspots can vary in length from 1 to several miles. Hotspot score is a value that combines the total density of WVC incidents (#/mile) and the statistical significance of clusters of incidents. You can see these data here: https://roadecology.ucdavis.edu/hotspots.

Real-Time, Automated Web-Map of WVC

To better inform the public and transportation agencies about highway segments with greater risk of WVC, we developed an easy-to-use, online system that provides two important sources of information: 1) mapped hotspots using legacy data (2015 to end of 2017); and 2) locations of recent (<1 week & <24 hours) locations of conflict with mule deer and other large mammals.
Figure 5. Zoomed in view of central San Francisco Bay Area showing incident densities and recent WVC incidents. The information box appears when the user clicks on a highway segment. https://roadecology.ucdavis.edu/hotspots.

We also developed the web-system so that it could be a continuous source of information for driver-assist, autonomous-vehicle, and app-based programs. For example, this information could be continuously fed into an app to inform drivers of locations of recent and long-term conflict, to inform their driving practice. It could also be used by driver-assist and autonomous vehicle systems to prioritize driver-warning and changes in sensitivity to the potential presence of large animals in the roadway.

Consequences of Collisions to Drivers and Society

Records analyzed show some individual drivers involved in collisions with animals experience emotional trauma and if the animal is larger, also face damage to their vehicle and injury (or even death) to themselves. Drivers may either collide with the animal, or swerve to avoid the animal and become involved in a collision with another vehicle or object (Table 1). We estimated the total cost of all WVC incidents to society, using summaries of types of accident (e.g., property
damage only, major injury), the loss of wildlife, and coefficients for each of these types of loss. Equivalent costs for accident types were obtained from the US Department of Transportation (USDOT, 2013) and a related project in South Dakota (Cramer et al., 2016). We only counted 1 fatality in data from CHP, but Caltrans reported 12 fatalities from collisions with wildlife for 2017, using data from CHP (http://www.dot.ca.gov/paffairs/pr/2018/prs/18pr072.html), so we used this number. We are not sure why this discrepancy occurs, but may be based on the fact that we retrieve our data from live incident reports by the CHP.

The rates of property damage, injury and death reported here are probably underestimates and may be superseded by more detailed information from other sources. For example, State Farm Insurance Co. estimates that there were >23,000 claims/year for collisions with deer in 2015-2016 (https://newsroom.statefarm.com/download/234883/allstates2015-16deerstats-finalpdf.pdf), whereas our calculations are based on >6,600 reported collisions during this time period. If these additional 16,000 collisions resulted in the same average property-damage-only cost as used below (USDOT, 2013), there would be an additional >$277 million cost to society (16,000 times $17,343/crash), resulting in a total estimated cost from WVC of ~$584 million/year.

From 2016 to 2017, we found an increase of ~11% in cost to society from WVC, which was 20% higher than the year before. This does not reflect a change in how the calculation was conducted, but instead an increase in the number of fatal collisions.

Table 1. Impact to drivers and estimated cost to society of reported collisions with animals on CA highways and certain major roads. Equivalent costs for accident types were obtained from the US Department of Transportation (2013) and a project in South Dakota (Cramer et al., 2016).

* This value includes both reported and estimated un-reported carcasses. Others have reported under-reporting rates for carcasses from collisions of 5-10 fold (e.g., Olson et al., 2014).

Consequences of Collisions to Large Mammals, Animal Populations & Individual Animals

The majority of reported traffic incidents involving an animal (Figure 2) were with mule deer (88%, Table 2), though at least 5 other mammals were also reported. In addition, these are just
species and number of animals that were included in a CHP incident report. Others have reported under-reporting rates of collisions with ungulates (e.g., deer) of 5 to 10 fold (Donaldson and Lafon, 2008; Olson et al., 2014). This suggests that as many as 25,000 to 50,000 mule deer were killed during collisions in 2015 and an unknown number of other species. This is supported by the State Farm Insurance Co estimate of >23,000 claims/year for collisions with deer in California, where collisions are likely to occur more often than claims (https://newsroom.statefarm.com/download/234883/allstates2015-16deerstats-finalpdf.pdf).

One important observation was that almost twice as many black bears were reported involved in accidents in 2017 (170 animals) than in 2016 (89 animals), or 2015 (83 animals). In addition, there were more collisions with mountain lions in 2017 (64 animals) than in 2016 (44 animals), or 2015 (38 animals). It is not obvious why this occurred, but it is a disturbing trend for both wildlife and drivers. Temporal and spatial patterns in conflict with different species can vary too, highlighting the need to study species separately when planning mitigation to protect them from harm from traffic and highways.

For people who have collided with an animal, some will have observed that the animal does not always die immediately. We found that 23% (n=1,495) of animals involved in incidents were reported as injured by responding law enforcement (Table 3). There were an additional 32% (n=2,119) with an unknown fate after being involved in a traffic incident. The rate of “unknown fate” for animals involved in a collision was much greater for elk, black bear and wild pig than mule deer, with the majority of these species having an unknown fate after collision. Only 149 animals were reported as dispatched by responding law enforcement officers, meaning that the remaining injured and some portion of the “unknown fate” animals stayed injured following the collision. This may still be an under-estimate of the total as there has been shown to be chronic under-reporting of collisions with ungulates, such as deer, in the US (Donaldson and Lafon, 2008; Olson et al., 2014).

In last year’s report, we suggested that injuring animals while driving and colliding with them could be considered cruelty. Although this may still be true, it makes sense to consider what solutions are available to reduce the unnecessary suffering of animals injured during collisions. A possible solution to this problem would be for the state to create a hotline where drivers can report an injured animal for potential rehabilitation, or in extreme cases, dispatch by CHP. Other countries (e.g., Germany, Sweden) have systems like this in place that could readily be adopted.

Regional/Local Focus

The need for projects that reduce the risk to driver safety and lives, property damage, and impacts to wildlife is critical. Building these projects will require a combination of Caltrans, county, regional, and legislative action and funding. This risk is greatest when there are more drivers driving fast through or near wildlife habitat, such as the San Francisco peninsula, the Sierra Nevada foothills and portions of Southern California (see following pages). In these areas traffic is also increasing, so the risk may also be increasing. For example, traffic volumes on I-280 in the vicinity of state highway 92 increased 5% from 2011 to 2015. The map below (Figure 6) shows the location of planned, state-funded projects in California, which are potential locations for wildlife-vehicle conflict mitigation. Unfortunately, there is not very good overlap between WVC hotspots and planned projects, including those planned under the Senate Bill 1 (SB1) fuel-tax funding source. This may not be surprising as neither the California Transportation Plan, nor SB1 mention widespread, adequate mitigation for this risk to driver safety and wildlife well-being. However, it is a problem that can be solved by spending SB 1 and other state funds on wildlife crossing projects. There is an immediate and urgent need for leadership on this issue in California and widespread construction of wildlife crossings solutions to reduce harm to drivers and wildlife. We suggest an expenditure rate of “1% for wildlife”, which equates to ~$50 million from transportation funds per year, coincidentally similar to the estimated cost per year of WVC.
Figure 6. Locations of WVC hotspots and planned projects under the State Transportation Improvement Program (STIP) and Senate Bill 1, fuel-tax funding.
San Francisco Bay Area, Regional Highway Hotspots

This map shows the hotspots of WVC incidents on select highways in the San Francisco Bay region (Figure 7). There are segments of highways that have high enough rates of WVC that if safety projects, such as fencing and wildlife crossings, were undertaken, they would pay for themselves through reduced WVC. This is especially true for I-280, the fencing of which would pay for itself in less than 1 year due to reduced WVC, property damage and driver injury. Many major WVC hotspot areas have no planned highway projects, but projects should be planned to reduce risk and harm.

Figure 7. Overlap of WVC hotspot areas with state-planned/funded highway projects in the San Francisco Bay Area.
Southern California, Regional Highway Hotspots
This map shows the clustering of WVC incidents on select highways in the northern Los Angeles basin and mountains (Figure 8). There are segments of highways that have high enough rates of WVC that mean if safety projects, such as fencing and wildlife crossings, were undertaken, they would pay for themselves through reduced WVC. There are several planned state-funded projects that could be used to build wildlife-crossing mitigation. There are also major hotspot areas with no planned highway projects, for which projects should be planned.

Figure 8. Overlap of WVC hotspot areas with state-planned/funded highway projects in the Southern California mountains north/west of Los Angeles.
Central California, Regional Highway Hotspots

This map shows the clustering of WVC traffic incidents on select highways in central-coastal California (Figure 9). There are segments of highways that have high enough rates of WVC that if safety projects, such as fencing and wildlife crossings, were undertaken, they would pay for themselves through reduced WVC.

Figure 9. Overlap of WVC hotspot areas with state-planned/funded highway projects in the Central California coast near Lompoc.
Sierra Nevada Foothills, Regional Highway Hotspots

This map shows the clustering of WVC incidents on select highways in the Sierra Nevada foothills (Figure 10). There are segments of highways that have high enough rates of WVC that mean if safety projects, such as fencing and wildlife crossings, were undertaken, they would pay for themselves through reduced WVC. There are several planned SB1-funded projects that could be used to build wildlife-crossing mitigation. There are also major hotspot areas with no planned highway projects, for which projects should be planned.

Appendix 1: (More) Detailed Methods

Data Sources
State highway network (SHN) and post-mile (PM) spatial datasets were obtained from Caltrans (http://www.dot.ca.gov/hq/tsip/gis/datalibrary/index.php#Highway). All traffic incident data from California Highway Patrol (CHP) resources, beginning in 2/2017, were collected by the UC Davis Road Ecology Center’s “California Highways Incident Processing System” (CHIPS) and ingested into a database. This database was then queried for incidents involving animals to create a dataset of Animal-Vehicle Conflict (AVC). The CHIPS AVC data includes collisions between vehicles and wildlife/domestic animals, carcasses found on highways, traffic hazards caused by animals, and other types of traffic incidents involving animals.

Each CHIPS data point contains several fields relating to the incident it represents. These fields include latitude, longitude, street or intersection name, animal species, and any details the CHP officer noted regarding the incident. Many points have multiple entries in the details field, meaning CHP documented updates to the incident as it progressed. These descriptions provide a thorough narrative of the incident, as well as details on the time that events occurred through the eyes of a CHP officer. Other fields in the AVC dataset are manually entered by the Road Ecology Center if they are included in the descriptions. Attributes include data like vehicle damage, driver and animal outcomes, and type of incident (e.g., swerve vs. collision).

CHIPS data represents incidents on California’s state, interstate, and federal highways. CHP does respond and document incidents on some unincorporated roads near highways, but incidents more than 50 meters from a highway were excluded from this study.

It is important to note that CHIPS AVC data are a subset of reported incidents on California highways. Unreported incidents and incidents on roads falling outside of the jurisdictions of CHP are not included. CHP has jurisdiction on all federal, state, and interstate highways and public roads in certain unincorporated areas. Therefore, CHIPS incidents are not a record of all AVC in California, but events which induce a documented report within CHP jurisdiction.

Of the AVC incidents, ~90% of the incidents involved mule deer. It can be inferred that animals large enough to cause damage to a vehicle are more likely to be reported to CHP. A minimal number of incidents involve small animals, such as pigeons, geese, and dogs. These are included in the analysis dataset, but do not represent the entirety of incidents with those smaller animals. Thus, this analysis does not represent AVC with smaller species, since those incidents are unlikely to be reported.

Assuming CHP consistently and accurately documents incidents across the state highway network, CHIPS data provides a spatially unbiased dataset of AVC involving large animals on California highways.

Geoprocessing
The datasets from the previous section were processed using the programming language R and ESRI ArcMap 10.6. The following geoprocessing steps were performed to create the automated hotspot analysis for AVC.
Network Segmentation

The basis for the AVC network analysis is the highway network. In order to create a uniform unit for analysis, one-mile segments were created for highway networks. The Caltrans SHN was used for the AVC analysis of California. The highway lines were split at each one-mile PM. This created a fairly uniform set of segments, split at well-known locations.

Assigning Incidents to Segments

A custom R script was written to assign AVC incident points to spatially corresponding road segments. The R script uses the snapPointsToLines function in the maptools library. Points >50 meters from any segment were filtered out. This approach did not attribute incidents to incorrect road segments. The number of AVC incidents for each segment was summed in an attribute field to the segment, which is the metric of primary importance in the WVC analysis. A maximum distance of 50 meters was chosen when snapping incident points to road segments. Since CHP often records data on road shoulders, and the highway network is often on the centerline of roads, or between separated highway lanes, and GPS receivers have an accuracy radius, point locations are usually a short distance away from network lines. However, incorporating points further than necessary would have included WVC points on roads not in the analysis, inaccurately inflating density distribution.

Clustering Statistics – Hotspot Score

To provide a different view of the spatial distribution of AVC along the network, the Getis0Ord Gi* statistic was used to statistically analyze clusters and to contribute to a hotspot score for each one-mile road segment. An R script ran a local Getis-Ord calculation for each segment on the network, analyzing the number of incidents snapped to each segment. The default neighbor radius is one mile (1609 meters), and a binary weighted matrix including the value of the segment. The script adds a Gi* z-score value to each segment, denoting if the segment is in a relative “hotspot” or “coldspot”.

The Gi* statistic is well-suited to identify hot and cold locations in density distribution, the resulting z-score is not clearly understood by all audiences. Moreover, some additional nuances of WVC distribution should be incorporated into an easily shared “hotspot score”.

Using the Gi* value, a “hotspot score” was created to more effectively communicate the results. First, segments with a) zero incident density or b) a negative Gi* value are assigned a hotspot score of zero. This avoids over-smoothing the score, to reveal highway segments with no incidents in a region of high incidents. Then, a percentile of each Gi* value within the distribution of remaining non-zero segments is calculated. Finally, an integer value from 1-10 is given to each segment by rounding up the percentiles. The hotspot score is a means of synthesizing incident density and spatial clustering, but presenting it in a way that is easily understood by all audiences. The process can be implemented on any network, and will categorize network segments into 10 equally sized categories, where each segment with a score greater than zero has incident densities and positive Gi* values.
